

Higher-order structure differs by species: human α -satellite is built from a multi-monomer unit, CEN180 and CentC repeat closer to the monomer.

Figure 5. Internal structure of one satellite array per species, taken from BWTandem's own calls. Left: pairwise window identity drawn as the upper triangle rotated 45 degrees, so x stays in genome coordinates and height is half the separation between the compared windows (1,000 bp windows, 250 bp step, shared canonical 13-mers). Bands parallel to the baseline are higher-order repeats: a band at height h means the array repeats every $2h$ bases. Right: self dot plot over the same interval at $k=21$; the sampling stride is set per panel so each carries a comparable number of points. Identity is containment against the smaller window, so a window straddling an array edge is not penalised for being half empty.
